# Hole and Antihole Detection in Graphs* 

Stavros D. Nikolopoulos ${ }^{\dagger} \quad$ Leonidas Palios ${ }^{\ddagger}$

#### Abstract

In this paper, we study the problems of detecting holes and antiholes in general undirected graphs and present algorithms for them, which, for a graph on $n$ vertices and $m$ edges, run in $O\left(n+m^{2}\right)$ time and require $O(n m)$ space; we thus provide a solution to the open problem posed by Hayward, Spinrad, and Sritharan in [12] asking for an $O\left(n^{4}\right)$ time algorithm for finding holes in arbitrary graphs. The key element of the algorithms is a special type of depthfirst search traversal which proceeds along $P_{4}$ S (i.e., chordless paths on four vertices) of the input graph. We also describe a different approach which allows us to detect antiholes in graphs that do not contain chordless cycles on 5 vertices in $O\left(n+m^{2}\right)$ time requiring $O(n+m)$ space. Our algorithms are simple and can be easily used in practice. Additionally, we show how our detection algorithms can be augmented so that they return a hole or an antihole whenever such a structure is detected in the input graph; the augmentation takes $O(n+m)$ time and space.

Keywords: hole, antihole, weakly chordal graph, coconnectivity.

## 1 Introduction

We consider finite undirected graphs with no loops or multiple edges. Let $G$ be such a graph and let $v_{0}, v_{1}, \ldots, v_{k-1}$ be a sequence of $k$ distinct vertices such that there is an edge from $v_{i}$ to $v_{(i+1)} \bmod { }_{k}$ (for all $i=0, \ldots, k-1$ ), and no other edge between any two of these vertices; we say that this is a chordless cycle on $k$ vertices. A hole is a chordless cycle on five or more vertices; an antihole is the complement of a hole.

Holes and antiholes have been extensively studied in many different contexts in algorithmic graph theory. Most notable examples are the weakly chordal graphs (also known as weakly triangulated graphs) [9, 10], which contain neither holes nor antiholes, and the strong perfect graph conjecture (Berge [1]), which states that a graph is perfect if and only if it contains no holes and no antiholes on an odd number of vertices (the recent proof of the conjecture by Chudnovsky et al. [4] has renewed the interest in the problem). Thus, finding a hole or an antihole in a graph efficiently is an important

graph-theoretic problem, both on its own and as a step in many recognition algorithms.

Several algorithms for detecting holes and antiholes in graphs have been proposed in the literature. The definition of holes and antiholes implies that such algorithms can be applied without error on the biconnected components of the input graph and of its complement, respectively, instead of the entire graph. Although this approach may lead to the fast detection of holes and antiholes in graphs with small biconnected components, it does not yield any gain in the asymptotic sense

The problem of determining whether a graph contains a chordless cycle on $k$ or more vertices, for some fixed value of $k \geq 4$, is solved in $O\left(n^{k}\right)$ time (Hayward [11]); Spinrad [16] provided an improved solution taking $O\left(n^{k-3} M\right)$ time, where $M \simeq n^{2.376}$ is the time required to multiply two $n \times n$ matrices. Note that the problem of determining whether a graph contains a chordless cycle on four or more vertices can be solved in $O(n+m)$ time $[9,15,18]$ (it is the well-known chordal graph recognition problem).

The algorithms of [11] and [16] can be used for the recognition of weakly chordal graphs in $O\left(n^{5}\right)$ and $O\left(n^{4.376}\right)$ time respectively. Further progress on the weakly chordal graph recognition problem includes the $O\left(n^{4}\right)$-time and $O(n m)$-space algorithm of Spinrad and Sritharan [17], and the $O\left(m^{2}\right)$-time and $O(n+m)$-space algorithm of Hayward, Spinrad, and Sritharan [12] and of Berry, Bordat, and Heggernes [2]. It is interesting to note that the algorithm of [12] produces a hole or an antihole certificate whenever the input graph is not weakly chordal. In the same paper, the authors posed as an open problem the designing of an $O\left(n^{4}\right)$-time algorithm to find a hole in an arbitrary graph.

In this paper, we study the above mentioned open problem and we present two algorithms, one for the detection of holes and another for the detection of antiholes in arbitrary graphs. Both algorithms run in $O\left(n+m^{2}\right)$ time and require $O(n m)$ space, and rely on the detection of a cycle satisfying certain conditions in the input graph or on its complement respectively. The existence of such a cycle is checked by means of a special depth-first search traversal, which we call $P_{4}$-DFS. We also describe another algorithm for the detection of antiholes in graphs that do not contain chordless cycles
on five vertices: the algorithm processes each edge of the input graph in order to determine whether the endpoints of the edge participate in an antihole, and relies on the computation of the co-connected components of subgraphs of the input graph; it runs in $O\left(n+m^{2}\right)$ time and takes $O(n+m)$ space. The same approach yields an $O\left(n^{2} m\right)$-time and $O\left(n^{2}\right)$-space algorithm for detecting holes in graphs that do not contain chordless cycles on five vertices.

Additionally, we describe how to augment our three detection algorithms so that they return a hole or an antihole in the case where such a structure exists in the input graph; the augmented hole (antihole, respectively) detection algorithm produces a hole (an antihole, respectively) in $O(n+m)$ additional time and $O(n+m)$ space. Finally, we note that, as a byproduct, our hole and antihole detection algorithms can be used for recognizing weakly chordal graphs leading to a solution that matches the best currently known time complexity for this problem.

## 2 Preliminaries

Let $G$ be a finite undirected graph with no loops or multiple edges. We denote by $V(G)$ and $E(G)$ the vertex set and edge set of $G$. The subgraph of a graph $G$ induced by a subset $S$ of vertices of $G$ is denoted by $G[S]$.

A path in $G$ is a sequence of vertices $v_{0} v_{1} \ldots v_{k}$ such that $v_{i} v_{i+1} \in E(G)$ for $i=0,1, \ldots, k-1$; we say that this is a path from $v_{0}$ to $v_{k}$ and that its length is $k$. A path is called simple if none of its vertices occurs more than once; it is called trivial if its length is equal to 0 . A simple path $v_{0} v_{1} \ldots v_{k}$ is chordless if $v_{i} v_{j} \notin E(G)$ for any two non-consecutive vertices $v_{i}$, $v_{j}$ in the path. Throughout the paper, the chordless path on $k$ vertices is denoted by $P_{k}$. In particular, a chordless path on 3 vertices is denoted by $P_{3}$ and a chordless path on 4 vertices is denoted by $P_{4}$. A sequence of vertices $v_{0} v_{1} \ldots v_{k-1}$ forms a cycle (resp. simple cycle) iff $v_{0} v_{k-1} \in E(G)$ and $v_{0} v_{1} \ldots v_{k-1}$ is a path (resp. simple path) in $G$; its length is equal to $k$. A simple cycle $v_{0} v_{1} \ldots v_{k-1}$ is said to be chordless if no edge $v_{i} v_{j}$ exists in $E(G)$ such that $|i-j| \neq 1 \bmod k$. The chordless cycle on $k$ vertices is denoted by $C_{k}$; in particular, $C_{5}$ is the chordless cycle on 5 vertices.

The neighborhood $N(x)$ of a vertex $x \in V(G)$ is the set of all the vertices of $G$ which are adjacent to $x$. The closed neighborhood of $x$ is defined as $N[x]:=$ $N(x) \cup\{x\}$. The neighborhood of a subset $S$ of vertices is defined as $N(S):=\left(\bigcup_{x \in S} N(x)\right)-S$ and its closed neighborhood as $N[S]:=N(S) \cup S$. The notion of the neighborhood can be extended to edges: for an
edge $e=x y$, the neighborhood (closed neighborhood) of $e$ is the vertex set $N(\{x, y\})$ (resp. $N[\{x, y\}])$ and is denoted by $N(e)$ (resp. $N[e])$. For an edge $e=x y$, we define the following three sets:

$$
\begin{aligned}
A(e ; x) & =N(x)-N[y] \\
A(e ; y) & =N(y)-N[x] \\
A(e) & =N(x) \cap N(y)
\end{aligned}
$$

clearly, these sets form a partition of the neighborhood $N(e)$ of the edge $e$.

We close this section by describing the coconnectivity problem which plays a crucial role in the antihole detection algorithm for graphs that do not contain a $C_{5}$, which we propose in this paper. The coconnectivity problem on a graph $G$ is that of finding the connected components of the complement $\bar{G}$; the connected components of $\bar{G}$ are called co-connected components (or co-components) of $G$. The co-components of a graph $G$ on $n$ vertices and $m$ edges can be computed in $O(n+m)$ time and space $[8,13,3]$.

## 3 Detecting Holes

The hole detection algorithm relies on the result stated in the following lemma.

Lemma 3.1. An undirected graph $G$ contains a hole if and only if $G$ contains a cycle $u_{0} u_{1} \ldots u_{k}$, where $k \geq 4$, such that $u_{i} u_{i+1} u_{i+2} u_{i+3}$ for each $i=0,1, \ldots, k-3$, and $u_{k-2} u_{k-1} u_{k} u_{0}$ are $P_{4} s$ of $G$.

Proof. $(\Longrightarrow)$ Suppose that $G$ contains a hole; then the vertices of the hole induce a cycle meeting the conditions of the lemma.
$(\Longleftarrow)$ Suppose now that $G$ contains a cycle as described in the lemma; let $v_{0} v_{1} \ldots v_{h}$ be the shortest such cycle. Then, this cycle is a hole:
a) since the cycle meets the conditions of the lemma, then $h \geq 4$, which implies that the cycle is of length at least equal to 5 ;
b) the cycle is chordless. Suppose for contradiction that there existed chords. With each chord $v_{i} v_{j}$, we associate its "length," which is defined as length $\left(v_{i} v_{j}\right)=|j-i|$; let $v_{\ell} v_{r}$, where $\ell<r$, be the chord of minimum length. Note that $r \geq \ell+4$; this follows from the fact that $r \geq 4$ (because $v_{0} v_{1} v_{2} v_{3}$ is a $P_{4}$ ) and the fact that $v_{r-3} v_{r-2} v_{r-1} v_{r}$ is a $P_{4}$. Then, $v_{r-2} v_{r-1} v_{r} v_{\ell}$ is a $P_{4}$ in $G$ because it is a path in $G, v_{r-2} v_{r} \notin E(G)$ (recall that $v_{r-3} v_{r-2} v_{r-1} v_{r}$ is a $P_{4}$ ), and $v_{\ell} v_{r-2} \notin E(G)$ and $v_{\ell} v_{r-1} \notin E(G)$ for otherwise these would be chords
whose length-value would be smaller than that of the chord $v_{\ell} v_{r}$, in contradiction to the minimality of length $\left(v_{\ell} v_{r}\right)$. Additionally, $v_{i} v_{i+1} v_{i+2} v_{i+3}$ is a $P_{4}$ for all $i=\ell, \ell+1, \ldots, r-3$. Thus, the cycle $v_{\ell} v_{\ell+1} \ldots v_{r}$ would meet the conditions of the lemma; as it would be shorter than the cycle $v_{0} v_{1} \ldots v_{h}$, this would contradict the fact that the latter cycle is the shortest such cycle. Hence, the cycle $v_{0} v_{1} \ldots v_{h}$ is chordless.

Therefore, $G$ contains a hole.
Our algorithm for the detection of holes applies Lemma 3.1. In particular, it uses a special type of depth-first search traversal, which we will call $P_{4}$-DFS: the $P_{4}$-DFS traversal works similarly to the standard depth-first search [6], except that, in its general step, it tries to extend a $P_{3} a b c$ into $P_{4} \mathrm{~s}$ of the form $a b c d$, then, for each such $P_{4}$, it proceeds extending the $P_{3} b c d$ into $P_{4} \mathrm{~s}$ of the form bcde, and so on. Unlike the standard depth-first search, the $P_{4}$-DFS traversal may proceed to a vertex that has been encountered before; however, it does not need to proceed to a $P_{3}$ that has been encountered before. If the $P_{4}$-DFS has at a given moment proceeded to traverse a sequence of $P_{3} \mathrm{~S} a b c$, $b c d, \ldots, w x y, x y z$, then we call the sequence of vertices $a, b, \ldots, y, z$ the current $P_{4}$-DFS path. Then, it is not difficult to see that the following holds:

Lemma 3.2. Suppose that the $P_{4}$-DFS traversal is applied on the input graph $G$. Then, if the current $P_{4}-D F S$ path $\rho$ is extended to a vertex which belongs to $\rho$, then $G$ contains a cycle meeting the conditions of Lemma 3.1.

Note that the cycle mentioned in Lemma 3.2 contains at least one $P_{4}$ and thus is of length at least equal to 5 .

In order to exhaustively search the input graph $G$, the $P_{4}$-DFS traversal starts from each $P_{3}$ of $G$. On the other hand, in order to prevent processing a $P_{3}$ which has been encountered before, it uses an auxiliary array not_in_hole $[(u, v), w]$, where $u, v, w \in V(G)$ and $u, v$ are adjacent in $G$; for each pair of adjacent vertices $u, v$, the array has entries not_in_hole $[(u, v), w]$ as well as not_in_hole $[(v, u), w]$ for every $w \in V(G)$, and hence its size is $2 m \cdot n$. The entry not_in_hole $[(u, v), w]$ is equal to 1 iff the vertices $u, v, w$ induce a $P_{3} u v w$ of $G$ which has been processed and found not to participate in a hole, otherwise it is equal to 0 (note that two entries of the array correspond to each $P_{3} u v w$, namely, not_in_hole $[(u, v), w]$ and not_in_hole $[(w, v), u])$. Additionally, in order to be able to test whether a vertex belongs to the current $P_{4}-$ DFS path, the algorithm uses another auxiliary array in_path [] of size $n$; for a vertex $v$, in_path [ $v$ ] is equal
to 1 if $v$ belongs to the current $P_{4}$-DFS path, and is 0 otherwise. Below, we give a detailed description of the algorithm when applied on a connected input graph $G$; the case of a disconnected input graph is discussed after the analysis of the algorithm. The algorithm assumes that $G$ is given in adjacency list representation, from which it computes the adjacency matrix of $G$ so that adjacency tests can be answered in constant time.

## Hole-Detection Algorithm

Input: a connected undirected graph $G$.
Output: yes, if $G$ contains a hole; otherwise, no.

1. Initialize the entries of the arrays not_in_hole[] and in_path[] to 0; compute the adjacency matrix A[] of $G$;
2. For each vertex $u$ of $G$ do
2.1 in_path $[u] \leftarrow 1$;
2.2 for each edge $v w$ of $G$ do
if $u$ is adjacent to $v$ and non-adjacent to $w$ and not_in_hole $[(u, v), w]=0$
then in_path $[v] \leftarrow 1$;
process $(u, v, w)$;
in_path $[v] \leftarrow 0$;
2.3 in_path $[u] \leftarrow 0$;
3. Print that $G$ does not contain a hole.
where the procedure process () is as follows:
process $(a, b, c)$
4. in_path $[c] \leftarrow 1$;
5. for each vertex $d$ adjacent to $c$ in $G$ do
2.1 if $d$ is adjacent to neither $a$ nor $b$ in $G$
then $\quad\left\{a b c d\right.$ is a $P_{4}$ of $\left.G\right\}$
2.2 if in_path $[d]=1$
then print that $G$ has a hole; Stop.
else if not_in_hole $[(b, c), d]=0$
then process $(b, c, d)$;
6. in_path $[c] \leftarrow 0$;
7. not_in_hole $[(a, b), c] \leftarrow 1$;
not_in_hole $[(c, b), a] \leftarrow 1$;
It is important to observe that the description of the procedure process() guarantees that from a $P_{3} a b c$ we proceed to a $P_{3} b c d$ only if $a b c d$ is a $P_{4}$ of the input graph $G$. Before returning, the procedure sets the corresponding entries of the array not_in_hole[], thus preventing a second call to the procedure on the same $P_{3}$. Additionally, a call process ( $a, b, c$ ) does not cause, for any depth of recursion, another call process $(a, b, c)$ or process $(c, b, a)$, because, for this to happen, the vertex $a$ (respectively, $c$ ) would be encountered again; then, the condition of the if statement in Step 2.2 of process ( ) would be found true and the algorithm would instantly terminate. Thus, the
procedure process() is called exactly once for each $P_{3}$ of $G$.

The correctness of the algorithm follows from Lemmas 3.1 and 3.2 and the following result.

Lemma 3.3. If for a $P_{3} a b c$ of the input graph $G$, the entry not_in_hole $[(a, b), c]$ is set to 1 , then the $P_{3} a b c$ does not participate in a hole of $G$.

Proof. For the entry not_in_hole $[(a, b), c]$ to be set to 1 , a call process $(a, b, c)$ or process $(c, b, a)$ needs to have been made; suppose without loss of generality that this is process $(a, b, c)$. The proof applies induction on the number of calls to the procedure process() that have returned before the assignment "not_in_hole $[(a, b), c] \leftarrow 1$ " in Step 4 of the call process $(a, b, c)$.

For the basis step, let us suppose that no calls to process() have returned. Then, no entry of the array not_in_hole[] has been set to 1 . Hence, no $P_{4}$ of the form $a b c d$ exists in $G$; if it existed, either the algorithm would have terminated (if $d$ belonged to the $P_{4}$-DFS path) or a call process ( $b, c, d$ ) would have been made, which should have returned for the control to proceed to Step 4. Therefore, since no $P_{4} a b c d$ exists in $G$, the $P_{3} a b c$ does not participate in a hole of $G$.

For the inductive hypothesis, we assume that the statement of the lemma is true for $P_{3}$ s for which the corresponding entries of the array not_in_hole[] have been set equal to 1 after fewer than $i_{0}>0$ calls to the procedure process() have returned. For the inductive step, we assume that the entry not_in_hole $[(a, b), c]$ corresponding to the $P_{3} a b c$ has been set equal to 1 after $i_{0}$ calls to the procedure process () have returned, and we show that the lemma holds for the $P_{3} a b c$. Suppose, for contradiction, that this is not the case; then, $a b c$ participates in a hole of $G$, which implies that there exists a vertex $x$ such that $a b c x$ is a $P_{4}$ of the hole. Clearly, this vertex $x$ has been considered in Step 2.2 of the execution of process $(a, b, c)$. It must be the case that in_path $[x]$ is not equal to 1 , for otherwise the algorithm would have terminated. Thus, if not_in_hole $[(b, c), x]$ is equal to 0 , a call process $(b, c, x)$ is made; if not_in_hole $[(b, c), x]$ is not equal to 0 , then it must have been set to 1 by a preceding call process $(b, c, x)$ or process $(x, c, b)$. In either case, this call to process() was completed before the execution of Step 4 of process ( $a, b, c$ ). Thus, the assignment "not_in_hole $[(b, c), x] \leftarrow 1$ " has been made after fewer than $i_{0}$ calls to process() have terminated; by the inductive hypothesis, we conclude that the $P_{3} b c x$ does not participate in any hole of $G$. This comes into contradiction with the fact that the $P_{4} a b c x$ is a $P_{4}$ of a hole of $G$. Therefore, the $P_{3} a b c$
does not participate in a hole of $G$. Our inductive proof is complete; the lemma follows.

Time and Space Complexity. Let $n$ and $m$ be the number of vertices and edges of the input graph $G$ respectively. Since $G$ is connected, then $n=O(m)$. Before analyzing the time complexity of each step of the algorithm, we turn to the procedure process(). We note that the procedure is called exactly once for each $P_{3}$ of $G$, i.e., $O(n m)$ times, and that, if we ignore the time taken by the recursive calls, a call process $(a, b, c)$ takes $O(|N(c)|+1)$ time by using the adjacency list of the vertex $c$ to retrieve $c$ 's neighbors, and by using the adjacency matrix A[] to answer adjacency tests in constant time. Therefore, the time taken by all the calls to the procedure process () is $O\left(m^{2}\right)$, since each quadruple of vertices $a, b, c, d$ where $a b c$ is a $P_{3}$ and $d$ is adjacent to $c$ is uniquely characterized by the ordered pair $((a, b),(c, d))$ where $(a, b)$ and $(c, d)$ are ordered pairs of adjacent vertices in $G$.

Step 1 of the main body of the algorithm clearly takes $O(n m)$ time. If the time taken by the calls to the procedure process() is ignored, Step 2 takes $O(n m)$ time; again, the adjacencies are checked in constant time by means of the adjacency matrix A[] of $G$. Step 3 takes constant time. Thus, the time complexity of the algorithm for a connected graph on $n$ vertices and $m$ edges is $O\left(m^{2}\right)$. The space needed is $O(n m): O(n)$ and $O(n m)$ for the arrays in_path[] and not_in_hole[] respectively, and $O\left(n^{2}\right)$ for the matrix A[] and the adjacency list representation of the input graph.

Summarizing, we have the following result.
Lemma 3.4. Let $G$ be a connected undirected graph on $n$ vertices and $m$ edges. Then, it can be determined whether $G$ contains a hole in $O\left(m^{2}\right)$ time and $O(n m)$ space.

The case of a disconnected input graph. If the input graph $G$ is disconnected, we work on each of its connected components; let $n_{i}$ and $m_{i}$ denote the number of vertices and edges of the $i$-th connected component respectively. The computation of the connected components takes $O(n+m)$ time [6], while processing each of them takes $O\left(m_{i}^{2}\right)$ time. Since $\sum_{i} m_{i}=m$, we have that $O\left(n+m^{2}\right)$ time suffices for detecting holes in any graph on $n$ vertices and $m$ edges. In this case, the space needed is $O\left(\sum_{i}\left(n_{i} m_{i}\right)\right)=O(n m)$. Therefore, we obtain the following theorem.

Theorem 3.1. Let $G$ be an undirected graph on $n$ vertices and $m$ edges. Then, it can be determined whether $G$ contains a hole in $O\left(n+m^{2}\right)$ time and $O(n m)$ space.

### 3.1 Providing a Certificate

The hole detection algorithm can be easily augmented so that it provides a certificate whenever it decides that the input graph $G$ contains a hole. In particular, we need the following:
(i) The updating of the entries of the array in_path [] is done so that they reflect the position of the corresponding vertex in the current $P_{4}$-DFS path. More specifically, in_path [ $v$ ] is set equal to $i$, if $v$ is the $i$-th vertex in the $P_{4}$-DFS path; this may necessitate replacing the call process $(a, b, c)$ by process ( $a, b, c, i$ ), if $c$ is the $i$-th vertex in the path.
(ii) The vertices in the current $P_{4}$-DFS path are stored in an array pathvertex [] in the order they appear along the path.
(iii) If the algorithm concludes that $G$ contains a hole, then the condition in Step 2.2 of the procedure process() during the execution of a call, say, process ( $a, b, c, k$ ), is found true for some vertex $d$; suppose that $d$ is located in the $j$-th position of the current $P_{4}$-DFS path. Then, the vertices located in positions $j, j+1, \ldots, k$ of the path form a cycle satisfying the conditions in the statement of Lemma 3.1. To isolate a hole, we call the following procedure get_hole $(j, k)$ before terminating in Step 2.2 of process $(a, b, c, k)$. The procedure computes the range $\left[i_{\text {min }}, i_{\text {max }}\right]$ of indices of the entries in the array pathvertex[] which store the vertices inducing a hole in $G$.

```
get_hole(j, k)
    imin}\leftarrowj;\quad\mp@subsup{i}{\operatorname{max}}{}\leftarrowk
    i}\leftarrow\mp@subsup{i}{min}{}
```

    repeat
        \(u \leftarrow\) pathvertex \([i] ;\)
        \(h \leftarrow i_{\text {max }}+1\);
        for each vertex \(x\) adjacent to \(u\) in \(G\) do
            if in_path \([x] \geq i+4\)
                and in_path \([x]<h\)
            then \(h \leftarrow\) in_path \([x]\);
        if \(h \leq i_{\max }\)
        then \(i_{\text {min }} \leftarrow i ; \quad i_{\text {max }} \leftarrow h ;\)
        \(i \leftarrow i+1 ;\)
    until \(i>i_{\text {max }}-4\);
    print the vertices in the entries \(i_{\text {min }}, i_{\text {min }}+1\),
    \(\ldots, i_{\max }\) of the array pathvertex [];
    The vertices printed induce a hole in $G$.
Note that, in each iteration of the repeat-until loop, at the end of the execution of the for loop, the variable $h$ is equal to the minimum index of any entry in the subarray pathvertex $\left[i+4 \ldots i_{\text {max }}\right]$ storing a neighbor
of pathvertex [i] in $G$, whenever such an entry exists, and is equal to $i_{\max }+1$ otherwise. The correctness of the computation follows from Lemma 3.5.

Lemma 3.5. The vertices printed by procedure get_hole() induce a hole in the input graph $G$.

Proof. Let $i_{\min }(t)$ and $i_{\max }(t)$ denote the values of $i_{\text {min }}$ and $i_{\max }$ at the beginning of the iteration of the repeatuntil loop for $i=t$, and let $\hat{\imath}_{\text {min }}$ and $\hat{\imath}_{\text {max }}$ be their final values. Clearly, the vertices printed by get_hole() induce a cycle. Moreover, its length is at least equal to 5 , since $i_{\max }(i) \geq i_{\min }(i)+4$ for every $i$; note that $k \geq j+4$ and that $h \geq i+4$. Finally, we show that the cycle is chordless. Suppose for contradiction that there existed a chord and suppose that it were incident on the vertices pathvertex [ $\ell$ ] and pathvertex $[r]$, where $\hat{\imath}_{\text {min }} \leq \ell<r \leq \hat{\imath}_{\text {max }}$ and $\ell \neq \hat{\imath}_{\text {min }}$ or $r \neq \hat{\imath}_{\text {max }}$ or both; then, $r-\ell<\hat{\imath}_{\text {max }}-\hat{\imath}_{\text {min }}$. The definition of the $P_{4}$-DFS traversal implies that every four consecutive vertices in the array pathvertex [] form a $P_{4}$, and thus $r-\ell \geq 4$. Hence, $\ell \leq r-4 \leq \hat{\imath}_{\text {max }}-4$, which, along with the fact that the value of $i_{\text {max }}$ never increases, implies that the repeat-until loop of the procedure get_hole( ) has been executed for $i=\ell$. At the end of the execution of the for loop when $i=\ell$, the variable $h$ would not exceed $r$, because the vertex pathvertex $[r]$ is adjacent to pathvertex $[\ell]$ in $G$, and $\ell+4 \leq r \leq \hat{\imath}_{\max } \leq i_{\max }(\ell)$; then, the condition " $h \leq i_{\text {max }}$ " would have been found true, and the variables $i_{\min }$ and $i_{\max }$ would have been set to $\ell$ and to an integer not exceeding $r$ respectively. This, however, comes into contradiction with the fact that $r-\ell<\hat{\imath}_{\text {max }}-\hat{\imath}_{\text {min }}$, since the value of $i_{\text {min }}$ never decreases and the value of $i_{\max }$ never increases.

The certificate computation takes $O(n+m)$ time: note that the vertices in the array pathvertex[] are distinct, and that their neighbors can be accessed in constant time per neighbor using the adjacency list representation of the input graph. The space required is linear in the size of the input graph. Therefore, we have:

Theorem 3.2. Let $G$ be an undirected graph on $n$ vertices and $m$ edges. The hole detection algorithm presented in this section can be augmented so that it provides a certificate that $G$ contains a hole, whenever it decides so of $G$. The certificate computation takes $O(n+m)$ time and $O(n+m)$ space.

## 4 Detecting Antiholes

Since an antihole is the complement of a hole, one can use the algorithm of the previous section on the
complement of a graph in order to determine whether it contains an antihole. Such an approach may however require $\Theta\left(n^{4}\right)$ time, where $n$ is the number of vertices of the graph, since the complement may have as many as $\Theta\left(n^{2}\right)$ edges. Below, we present an algorithm for the detection of antiholes which applies the $P_{4}$-DFS traversal on the complement of the input graph $G$ without however computing the complement explicitly and which takes $O\left(n+m^{2}\right)$ time when $G$ has $n$ vertices and $m$ edges. The algorithm uses an array not_in_antihole $[(a, b), c]$, where $a, b, c \in$ $V(G)$ and $a b \in E(G)$, and thus is of size $2 m \cdot n$; not_in_antihole $[(a, b), c]$ is equal to 1 iff $a c b$ is a $P_{3}$ of $\bar{G}$ which has been found not to participate in an antihole of $G$, and is 0 otherwise. The input graph $G$ is assumed to be connected; if $G$ is disconnected, then we apply the algorithm on each of $G$ 's connected components.

## Antihole-Detection Algorithm

Input: a connected undirected graph $G$.
Output: yes, if $G$ contains an antihole; otherwise, no.

1. Initialize the entries of arrays not_in_antihole[] and in_path[] to 0; compute the adjacency matrix of $G$;
2. For each vertex $u$ of $G$ do
2.1 in_path $[u] \leftarrow 1$;
2.2 for each edge $v w$ of $G$ do
if $u$ is adjacent to neither $v$ nor $w$ and not_in_antihole $[(v, w), u]=0$
then in_path $[v] \leftarrow 1$;
process $(v, u, w)$;
in_path $[v] \leftarrow 0$;
2.3 in_path $[u] \leftarrow 0$;
3. Print that $G$ does not contain an antihole.
where the procedure process () is as follows:
process ( $a, b, c$ )
4. in_path $[c] \leftarrow 1$;
5. for each vertex $d$ adjacent to $b$ in $G$ do
2.1 if $d$ is adjacent to $a$ and non-adjacent to $c$ then $\left\{a b c d\right.$ is a $P_{4}$ of $\left.\bar{G}\right\}$
$2.2 \quad$ if in_path $[d]=1$
then print that $G$ has an antihole; Stop.
else if not_in_antihole $[(b, d), c]=0$ then process $(b, c, d)$;
6. in_path $[c] \leftarrow 0$;
7. not_in_antihole $[(a, c), b] \leftarrow 1$;
not_in_antihole $[(c, a), b] \leftarrow 1$;
Note that for a call process $(a, b, c), a$ and $c$ are adjacent in $G$, while $b$ is adjacent to neither $a$ nor $c$. So, if there exists a vertex $d$ such that $d$ is adjacent to $a$ and $b$ and not adjacent to $c$, then the vertices $a, b, c, d$ induce the $P_{4} a b c d$ in $\bar{G}$.

The correctness of the algorithm is established as in the case of the hole detection algorithm of the previous section.

Time and Space Complexity. Similarly to the case of the hole detection algorithm, we obtain the result stated in Theorem 4.1; observe that if we ignore the time taken by the recursive calls, the execution of the call process $(a, b, c)$ takes $O(|N(b)|+1)$ time, and that each quadruple of vertices $a, b, c, d$ where $a b c$ is a $P_{3}$ of $\bar{G}$ and $d$ is adjacent to $b$ in $G$ is uniquely characterized by the ordered pair $((a, c),(b, d))$, where $(a, c)$ and $(b, d)$ are ordered pairs of adjacent vertices in $G$.

Theorem 4.1. Let $G$ be an undirected graph on $n$ vertices and $m$ edges. Then, it can be determined whether $G$ contains an antihole in $O\left(n+m^{2}\right)$ time and $O(n m)$ space.

### 4.1 Providing a Certificate

Similarly to the hole detection algorithm, the above algorithm can be easily augmented so that it provides a certificate whenever it decides that the input graph $G$ contains an antihole. In particular,
(i) we use arrays in_path[] and pathvertex[] as described in Section 3.1;
(ii) if the algorithm concludes that $G$ contains an antihole, then the condition in Step 2.2 of the procedure process ( ) during the execution of a call, say, process ( $a, b, c, k$ ), is found true for some vertex $d$; suppose that $d$ is located in the $j$-th position of the current $P_{4}$-DFS path. Then, the vertices located in positions $j, j+1, \ldots, k$ of the path form a cycle in $\bar{G}$ satisfying the conditions in the statement of Lemma 3.1. To isolate an antihole, we call the following procedure get_antihole ( $j, k$ ) before terminating in Step 2.2 of process $(a, b, c, k)$; the procedure computes the range $\left[i_{\text {min }}, i_{\text {max }}\right]$ of indices of the entries in the array pathvertex[] which store the vertices inducing an antihole in $G$.

```
get_antihole ( \(j, k\) )
    \(i_{\min } \leftarrow j ; \quad i_{\max } \leftarrow k ;\)
    \(i \leftarrow i_{\text {min }} ;\)
    repeat
        \(u \leftarrow\) pathvertex \([i] ;\)
        \(h \leftarrow i+4 ;\)
        while \(h \leq i_{\max }\)
        and pathvertex \([h]\) is adjacent to \(u\) do
            \(h \leftarrow h+1 ;\)
        if \(h \leq i_{\max } \quad\{a\) non-neighbor was found \(\}\)
        then \(i_{\text {min }} \leftarrow i ; \quad i_{\text {max }} \leftarrow h ;\)
```

```
    \(i \leftarrow i+1 ;\)
until \(i>i_{\max }-4\);
print the vertices in the entries \(i_{\text {min }}, i_{\text {min }}+1\),
\(\ldots, i_{\max }\) of the array pathvertex [];
```

The vertices printed induce an antihole in $G$.
It is not difficult to see that, for each value of $i$, when the condition of the while loop is found false, the variable $h$ is equal to the minimum index of any entry in the subarray pathvertex $\left[i+4 \ldots i_{\max }\right]$ storing a non-neighbor of pathvertex $[i]$ in $G$, whenever such an entry exists, and is equal to $i_{\max }+1$ otherwise. The correctness of the procedure get_antihole() follows from an argument similar to that used to prove Lemma 3.5; as in the case of holes, the value of $i_{\text {min }}$ never decreases, whereas the value of $i_{\text {max }}$ never increases.

The procedure requires $O(n+m)$ time: the initialization assignments take $O(1)$ time; during the execution of the repeat-until loop for the vertex $u$ stored in pathvertex[i], the condition of the while loop is checked at most $|N(u)|$ times (it is found false at the first-encountered non-neighbor of $u$ ) and thus the while loop takes $O(N(u)$ ) time (thanks to the adjacency matrix of $G$ ), while $O(1)$ time suffices for the remaining assignments. Since the vertices in the array pathvertex[] are distinct, it follows that the procedure get_antihole () takes $O(n+m)$ time. The space required is linear in the size of the input graph. Therefore, the following theorem holds:

Theorem 4.2. Let $G$ be an undirected graph on $n$ vertices and $m$ edges. The antihole detection algorithm presented in this section can be augmented so that it provides a certificate that $G$ contains an antihole, whenever it decides so of $G$. The certificate computation takes $O(n+m)$ time and $O(n+m)$ space.

## 5 Detecting Antiholes in Graphs that do not Contain a $C_{5}$

Antiholes in general graphs can be detected by taking advantage of the following property:

Lemma 5.1. Let $G$ be an undirected graph. Then, $G$ contains an antihole if and only if there exists an edge $e=x y$ of $G$ and a vertex $u \in V(G)-N[e]$ such that in the complement of the subgraph of $G$ induced by $N(e) \cap N(u)$ there exists a path from a vertex in $A(e ; x)$ to a vertex in $A(e ; y)$.

Proof. $(\Longrightarrow)$ Suppose that $G$ contains an antihole and let this be the complement of the hole $v_{0} v_{1} \ldots v_{k}$, where $k \geq 4$. Then, the vertices $v_{1}$ and $v_{k}$ are adjacent in
$G$; let $e$ be the edge of $G$ connecting them. Then, $v_{0} \in V(G)-N[e], v_{2} \in A\left(e ; v_{k}\right), v_{k-1} \in A\left(e ; v_{1}\right)$, and $\left\{v_{2}, \ldots, v_{k-1}\right\} \subseteq N(e) \cap N\left(v_{0}\right)$; these and the fact that the sequence $v_{k-1}, \ldots, v_{2}$ induces a path in $\bar{G}$ imply that the conditions of the lemma hold for the edge $v_{1} v_{k}$ of $G$ and the vertex $v_{0}$.
$(\Longleftarrow)$ Suppose now that there exists an edge $e=x y$ of $G$ and a vertex $u \in V(G)-N[e]$ such that in the complement of the subgraph $G[N(e) \cap N(u)]$ there exists a path from a vertex in $A(e ; x)$ to a vertex in $A(e ; y)$. Let $p_{0} p_{1} \ldots p_{k}$ be a shortest such path; that is, $p_{0} \in$ $A(e ; x) \cap N(u), p_{k} \in A(e ; y) \cap N(u), p_{i} \in A(e) \cap N(u)$ for all $i=1, \ldots, k-1$, and $p_{i} p_{j} \in E(G)$ for $0 \leq i<j-1 \leq$ $k-1$. Then, the subgraph $G\left[\left\{x, u, y, p_{0}, p_{1}, \ldots, p_{k}\right\}\right]$ of $G$ is the complement of a chordless cycle of length at least 5 ; in other words, $G$ contains an antihole.

Lemma 5.1 readily implies an antihole detection algorithm which for a graph $G$ on $n$ vertices and $m$ edges runs in $\Theta\left(n m^{2}\right)$ time in the worst case: for the appropriate pairs of an edge $e=x y$ and a vertex $u$, we compute the co-components of the subgraph $G[N(e) \cap$ $N(u)]$ and check whether any of them contains vertices from both $A(e ; x)$ and $A(e ; y)$; as there may be as many as $\Theta(n m)$ such pairs, and for each one of them $\Theta(n+m)$ time may be needed and suffices for the above mentioned computations, the overall time complexity is $\Theta\left(n m^{2}\right)$. An improved algorithm can be obtained for graphs not containing $C_{5} \mathrm{~s}$, for which the following fact holds.

FACT 5.1. Let $G$ be an undirected graph which does not contain a $C_{5}$, and let $e=x y$ be an edge of $G$. Then, for every pair of vertices $a$ and $b$ such that $a \in A(e ; x)$, $b \in A(e ; y)$, and $(N(a) \cap N(b))-N[e] \neq \emptyset$, it holds that $a$ and $b$ are adjacent in $G$.

Proof. Let $w$ be any vertex in $(N(a) \cap N(b))-N[e]$; clearly, $w a, w b \in E(G)$, and $w x, w y \notin E(G)$. If the vertices $a$ and $b$ were not adjacent in $G$, then the subgraph of $G$ induced by $a, x, y, b$, and $w$ would be a $C_{5}$, a contradiction.

In light of Fact 5.1, for any edge $e=x y$ and any vertex $u \in V(G)-N[e]$ of a graph $G$ that does not contain a $C_{5}$, any path from a vertex in $A(e ; x)$ to a vertex in $A(e ; y)$ in the complement of the subgraph of $G$ induced by $N(e) \cap N(u)$ is of length at least 2 and contains a vertex in $A(e)$. Then, instead of computing such a path we need only determine if there exist vertices $a \in A(e ; x) \cap N(u), b \in A(e ; y) \cap N(u)$, and $v \in A(e) \cap N(u)$ such that $v, a$ belong to the same co-component of the subgraph $G[N(x) \cap N(u)]$, and $v, b$ belong to the same co-component of the subgraph $G[N(y) \cap N(u)]$; see Figure 1: $C$ and $D$ denote the

Figure 1
co-components of the subgraphs $G[N(x) \cap N(u)]$ and $G[N(y) \cap N(u)]$ containing $v$ and $a$, and $v$ and $b$ respectively, and the dotted paths indicate chordless paths in the complements of these subgraphs. We show next that the existence of such vertices $v, a$, and $b$ is equivalent to the existence of an antihole in $G$.

Lemma 5.2. Let $G$ be an undirected graph which does not contain a $C_{5}$. Then, $G$ contains an antihole if and only if there exists an edge $e=x y$ of $G$ and vertices $u \in V(G)-N[e], a \in A(e ; x) \cap N(u), b \in A(e ; y) \cap N(u)$, and $v \in A(e) \cap N(u)$ such that $a, v$ belong to the same co-component of the subgraph $G[N(x) \cap N(u)]$, and $b, v$ belong to the same co-component of the subgraph $G[N(y) \cap N(u)]$.

Proof. ( $\Longrightarrow$ ) Suppose that $G$ contains an antihole. Since $G$ does not contain a $C_{5}$, the antihole is of length at least 6 ; let it be the complement of the hole $v_{0} v_{1} \ldots v_{k}(k \geq 5)$. The vertices $v_{1}$ and $v_{k}$ are adjacent in $G$; if $e$ is the edge of $G$ connecting them, then, $v_{0} \in V(G)-N[e], v_{2} \in A\left(e ; v_{k}\right) \cap N\left(v_{0}\right), v_{k-1} \in$ $A\left(e ; v_{1}\right) \cap N\left(v_{0}\right)$, and $\left\{v_{3}, \ldots, v_{k-2}\right\} \subseteq A(e) \cap N\left(v_{0}\right)$. Since $k \geq 5$, it is easy to see that the conditions of the lemma hold for $v_{1}, v_{k}, v_{0}, v_{k-1}, v_{2}, v_{3}$ in place of $x, y, u, a, b, v$ respectively.
$(\Longleftarrow)$ Suppose now that there exists an edge $e=x y$ of $G$ and vertices $u, a, b, v$ as described in the statement of the lemma. Then, in the complement of the subgraph of $G$ induced by $N(e) \cap N(u)$ there exists a path from vertex $a \in A(e ; x)$ to vertex $b \in A(e ; y)$. Then, by Lemma 5.1, $G$ contains an antihole.

We give below a detailed description of the antihole detection algorithm for a connected input graph $G$; for disconnected input graphs, we apply the algorithm on each of their connected components.

Antihole-Detection Algorithm for Graphs that do not contain a $C_{5}$
Input: a connected undirected graph $G$ that does not contain a $C_{5}$.

Output: yes, if $G$ contains an antihole; otherwise, no.

## 1. For each vertex $u$ of $G$ do

1.1 for each vertex $w$ not adjacent to $u$ in $G$ do
1.1.1 compute the set $N_{u, w}=N(u) \cap N(w)$;
1.1.2 compute the co-components of $G\left[N_{u, w}\right]$;
1.1.3 store the set $N_{u, w}$ as a list of vertex records, ordered by vertex index, where each vertex $z \in N_{u, w}$ is associated with the representative $\operatorname{cc}\left(N_{u, w} ; z\right)$ of the co-component to which it belongs;
1.2 for each edge $e=x y$ of $G$ s.t. $x, y \notin N[u]$ do $\{x, y \notin N[u]$ is equivalent to $u \in V(G)-N[e]\}$
1.2.1 $\left\{\right.$ mark the co-components of $\left.G\left[N_{u, x}\right]\right\}$
$\{$ containing a vertex in $A(e ; x)\}$
for each vertex $w \in N_{u, x}$ do mark1 $[w] \leftarrow 0 ;$
for each vertex $w \in N_{u, x}-N_{u, y}$ do \{mark the representative $\}$ $\operatorname{mark1}\left[\operatorname{cc}\left(N_{u, x} ; w\right)\right] \leftarrow 1$;
1.2.2 \{ mark the co-components of $\left.G\left[N_{u, y}\right]\right\}$
$\{$ containing a vertex in $A(e ; y)\}$
for each vertex $w \in N_{u, y}$ do $\operatorname{mark} 2[w] \leftarrow 0 ;$
for each vertex $w \in N_{u, y}-N_{u, x}$ do \{mark the representative $\}$ $\operatorname{mark2}\left[\operatorname{cc}\left(N_{u, y} ; w\right)\right] \leftarrow 1$;
1.2.3 for each vertex $v \in N_{u, x} \cap N_{u, y}$ do if mark1 $\left[\operatorname{cc}\left(N_{u, x} ; v\right)\right]=1$
and $\operatorname{mark} 2\left[\operatorname{cc}\left(N_{u, y} ; v\right)\right]=1$ then print that $G$ contains an antihole; Stop;
2. Print that $G$ does not contain an antihole.

The correctness of the algorithm follows from Lemma 5.2: for a vertex $u$ of $G$ and an edge $e=x y$ such that $x, y \notin N[u]$, then $A(e ; x) \cap N(u)=N_{u, x}-N_{u, y}$, $A(e ; y) \cap N(u)=N_{u, y}-N_{u, x}$, and $A(e) \cap N(u)=N_{u, x} \cap$ $N_{u, y}$; moreover, the condition "if mark1 $\left[\operatorname{cc}\left(N_{u, x} ; v\right)\right]=$ 1 and mark2[cc $\left.\left(N_{u, y} ; v\right)\right]=1 "$ and the fact that the vertex $v$ belongs to $N_{u, x} \cap N_{u, y}$ imply that in the complement of $G\left[N_{u, x}\right]$ there exists a path from $v$ to a vertex in $A(e ; x)$ and that in the complement of $G\left[N_{u, y}\right]$ there exists a path from $v$ to a vertex in $A(e ; y)$.

Time and Space Complexity. Let $n$ and $m$ be the number of vertices and edges of the input graph $G$; since $G$ is connected, $n=O(m)$. Step 1.1.1 can be completed in $O(n)$ time, while the construction of $G\left[N_{u, w}\right]$ and the computation of its co-components can be done in $O\left(\left|N_{u, w}\right|^{2}\right)$ time $[8,13,3]$. Since $\left|N_{u, w}\right| \leq \min \{|N(u)|,|N(w)|\}$, we have that $\left|N_{u, w}\right|^{2} \leq$
$|N(u)| \cdot|N(w)| ;$ thus, for a vertex $u$ of $G$, Step 1.1.2 takes $O(n)+\sum_{w} O(|N(u)| \cdot|N(w)|)=O(m|N(u)|)$ time ${ }^{1}$. The construction of the list storing $N_{u, w}$ in Step 1.1.3 can be done in $O(|N(u)|)$ time by traversing the adjacency list of $u$, by collecting those vertices that belong to $N_{u, w}$, and by updating the co-component representative information; the ordering by vertex index comes for free, had we sorted the adjacency lists of the vertices in $G$ by vertex index, something which can be achieved in $O(n+m)$ time using radix sorting during a preprocessing phase.

The sorting of the lists representing the sets $N_{u, w}$ implies that determining which vertices belong to $N_{u, x}-$ $N_{u, y}, N_{u, y}-N_{u, x}$, and $N_{u, x} \cap N_{u, y}$ can be achieved by simply traversing the lists for $N_{u, x}$ and $N_{u, y}$ in lockstep fashion. Then, each execution of Step 1.2 takes $O(|N(u)|)$ time, since $N_{u, x}, N_{u, y} \subseteq N(u)$. Thus, for a vertex $u$ of $G$, Step 1.2 takes $\sum_{e} O(|N(u)|)=$ $O(m|N(u)|)$ time. Step 2 takes constant time. In total, the entire execution of the algorithm on $G$ takes $O\left(\sum_{u} O(n+m+m|N(u)|)\right)=O\left(m^{2}\right)$ time.

Let us now turn to the space complexity of the algorithm. The adjacency list representation of the input graph requires $O(n+m)$ space. For an iteration of the for loop in Step 1, we need: $O(n)$ space to store $N_{u, w}$ and the re-indexing arrays, and $O(n+m)$ space to store $G\left[N_{u, w}\right]$, both reusable in each iteration of the for loop in Step 1.1; $\sum_{w} O\left(1+\left|N_{u, w}\right|\right)=O(n+m)$ space to store the list representations of the sets $N_{u, w}$ for all $w \in V(G)-N[u] ; O(n)$ space for the arrays mark1[] and mark 2[] , reusable in each iteration of the for loop in Step 1.2. This space can be reused from iteration to iteration of the for loop in Step 1, so that the space complexity of the algorithm is $O(n+m)$.

In summary, our antihole detection algorithm runs in $O\left(m^{2}\right)$ time using $O(n+m)$ space when applied on a connected undirected graph on $n$ vertices and $m$ edges. If the input graph is disconnected, then we apply the algorithm on each of its connected components. Since the connected components of a graph can be computed in time and space linear in the size of the graph [6] and since these components are pairwise vertex- and edgedisjoint, we obtain the following result.

Theorem 5.1. Let $G$ be an undirected graph on $n$ vertices and $m$ edges which does not contain a $C_{5}$. Then, it can be determined whether $G$ contains an antihole in $O\left(n+m^{2}\right)$ time and $O(n+m)$ space.

[^1]
### 5.1 Providing a Certificate

Like the previous algorithms, this algorithm too can be augmented so that it provides a certificate whenever it decides that the input graph $G$ contains an antihole. In particular, if $G$ contains an antihole, then whenever the algorithm finds that, for a vertex $u$ and an edge $e=x y$ of $G$ such that $x, y \notin N[u]$, there exists a vertex $v \in$ $N_{u, x} \cap N_{u, y}$ for which mark1 $\left[\operatorname{cc}\left(N_{u, x} ; v\right)\right]=1$ and $\operatorname{mark} 2\left[\operatorname{cc}\left(N_{u, y} ; v\right)\right]=1$, it executes the following in Step 1.2.3 before terminating:
(i) computes the subgraph $G[N(e) \cap N(u)]$;
(ii) uses a dummy vertex $s$ and makes it adjacent to all the vertices of the subgraph except for those in $N_{u, x}-N_{u, y} ;$
(iii) runs BFS on the complement of the resulting graph starting at $s$ until a vertex, say, $b$, in $N_{u, y}-N_{u, x}$ is encountered;

It is not difficult to see that if the path on tree edges from $s$ to $b$ in the BFS-tree of Step (iii) is $s v_{1} v_{2} \ldots v_{k} b$, then the vertices $x, u, y, v_{1}, \ldots, v_{k}, b$ induce an antihole in $G$ of length at least 6 (since $G$ does not contain a $C_{5}$, then $k \geq 2$ in accordance with Fact 5.1).

The computation of the adjacency list representation of the subgraph $G[N(e) \cap N(u)]$ can be done in $O(n+m)$ time and space by using a copy of the adjacency list representation of $G$ and by removing from it all unnecessary lists and vertex records. The addition of the dummy vertex $s$ can be done in $O(n)$ time and space. Executing BFS on the complement of the resulting graph can be done in time and space linear in the size of the graph, i.e., in $O(n+m)$ time and space (see $[8,13,14])$. Finally, the path on tree edges needed to complete the antihole can be easily obtained in time linear in its length if the BFS-tree is represented by means of parent pointers. Therefore, we have:

Theorem 5.2. Let $G$ be an undirected graph on $n$ vertices and $m$ edges which does not contain a $C_{5}$. The antihole detection algorithm presented in this section can be augmented so that it provides a certificate that $G$ contains an antihole, whenever it decides so of $G$. The certificate computation takes $O(n+m)$ time and space.

Remark. Since an antihole is the complement of a hole and the complement of a $C_{5}$ is also a $C_{5}$, one can detect whether a graph $G$, which does not contain a $C_{5}$, contains a hole by applying the above algorithm on its complement $\bar{G}$; this results into an $O\left(n^{4}\right)$-time and $O\left(n^{2}\right)$-space algorithm. If however the operation of the algorithm on $\bar{G}$ is interpreted in terms of $G$ so that
$\bar{G}$ is not constructed explicitly, then it can be shown that the algorithm runs in $O\left(n^{2} m\right)$ time and requires $O\left(n^{2}\right)$ space. This result indicates that the same approach results in a hole detection algorithm which in the worst case proves asymptotically more timeand space-consuming than the corresponding antihole detection algorithm. This seems to be due to the fact that checking whether a graph contains an antihole of length $k$ requires that certain $\Theta\left(k^{2}\right)$ edges exist and that certain $k$ edges are missing, whereas in the case of a hole of length $k$, one needs to verify that $k$ edges exist and $\Theta\left(k^{2}\right)$ edges are missing; in the former case, the cost of checking the non-existence of the $k$ edges can be paid for by the $\Theta\left(k^{2}\right)$ existing edges, something which does not hold in the latter case.

## 6 Concluding Remarks

We have presented algorithms for detecting holes and antiholes in general undirected graphs. For an input graph on $n$ vertices and $m$ edges, both algorithms run in $O\left(n+m^{2}\right)$ time and require $O(n m)$ space. The algorithms can be augmented so that they return a hole or an antihole (whenever such a structure exists in the graph) in $O(n+m)$ additional time and space. We have also described an antihole detection algorithm for graphs not containing a $C_{5}$ which runs in $O\left(n+m^{2}\right)$ time and requires only $O(n+m)$ space.

The obvious open problem is to design algorithms for finding a hole and/or an antihole in general graphs with improved time and/or space complexity; note that all the $P_{3}$ s participating in $P_{4}$ s of a graph on $n$ vertices and $m$ edges can be computed in $O(n m)$ time [14]. It is worth mentioning that $o\left(n+m^{2}\right)$-time algorithms for both problems would imply an improvement on the currently best algorithms for recognizing weakly chordal graphs [12, 2].

We also pose as an open problem the construction of $O\left(n+m^{2}\right)$-time algorithms for detecting whether a graph contains a $C_{5}$. None of our algorithms seems to be modifiable to handle this special case while maintaining the $O\left(n+m^{2}\right)$ time complexity. We note that, due to our antihole detection algorithm for graphs that do not contain a $C_{5}$, an $O\left(n+m^{2}\right)$-time and $O(n+m)$-space algorithm for detecting a $C_{5}$ would imply an antihole detection algorithm for general graphs of the same time and space complexity.

Finally, in light of the "strong perfect graph theorem" [4], it would be very interesting to come up with efficient algorithms for the detection of odd-length holes and/or odd-length antiholes in general graphs. For a graph on $n$ vertices, the currently fastest algorithms for these problems run in $O\left(n^{9}\right)$ time $[5,7]$.

[^1]:    ${ }^{1}$ Note that working on the subgraph $G\left[N_{u, w}\right]$ requires reindexing of vertices, i.e., mapping the indices $1, \ldots, n$ of vertices in $G$ to the indices $1, \ldots,\left|N_{u, w}\right|$ of vertices in $G\left[N_{u, w}\right]$ and vice versa; this can be done by using two arrays of $O(n)$ total space which take $O(n)$ time to initialize and constant time to answer each re-indexing request.
